

ECE 6552 – Lecture 14

MOTIVATING FEEDBACK LINEARIZATION

March 3 2026

Overview:

- Control Systems and Control Objectives
- Motivating Feedback Linearization

Additional Reading

- Khalil Chapter 12 (Feedback Control)
- Khalil Chapter 13 (Feedback Linearization)

Course Roadmap

Proposed Roadmap:

- Lecture 14-18: Feedback Linearization
- Lecture 19-21: Control Lyapunov Functions
- Lecture 22-24: Control Barrier Functions
- Lecture 25: Exam 2 Review
- Lecture 26: Hybrid Zero Dynamics

Motivating Feedback Linearization

Feedback linearization is an extremely powerful tool in nonlinear control because it allows one (under certain conditions) to *exactly* linearize a nonlinear system via nonlinear control.

Control Systems and Control Objectives

Definition: Control System. Consider an open and connected set $D \subseteq \mathbb{R}^n$ and a set of admissible control inputs $U \subset \mathbb{R}^m$. A control system is given by a differential equation:

$$\dot{x} = f(x, u), \quad x \in D, u \in U$$

where $f : D \times U \rightarrow \mathbb{R}^n$ is a C^1 function

Definition: Affine Control System. A control system is an affine control system (or control-affine) if it can be written in the form:

$$\dot{x} = f(x) + g(x)u$$

where $f : D \rightarrow \mathbb{R}^n$ and $g : D \rightarrow \mathbb{R}^{n \times m}$ are C^1 functions. Here, f is sometimes called the *drift* and g is sometimes called the *actuation matrix* or *input matrix*.

Definition: Outputs. An output is a differentiable function $y : D \rightarrow \mathbb{R}^k$, sometimes written in vector form:

$$y(x) = \begin{bmatrix} y_1(x) \\ \vdots \\ y_k(x) \end{bmatrix} \in \mathbb{R}^k$$

Goal of Control: Control objectives can be mathematically encoded through the use of *outputs*. Explicitly, the goal is to define a feedback control law $u : D \rightarrow U$ such that any solution $x(t)$ of the resulting closed loop system:

$$\dot{x} = f_{cl}(x) = f(x) + g(x)u(x)$$

drives the outputs to zero (drives $y(x(t)) \rightarrow 0$ as $t \rightarrow \infty$).

Example: One standard control objective is to drive the system to a desired state $x_{\text{des}} \in \mathbb{R}^n$. In this case:

$$y(x) = x - x_{\text{des}}$$

where $y : D \rightarrow \mathbb{R}^n$ and thus $k = n$.

Virtual Constraints: We can achieve “output-based tracking” by defining a set of *virtual constraints*:

$$y(x, t) = y_a(x) - y_{\text{des}}(t, \alpha)$$

where $y_a(x)$ is the actual output and $y_{\text{des}}(t, \alpha)$ is the desired output, which is a function of time and some parameterization α . We can remove the dependence on time using a *parameterization of time* $\tau : D \rightarrow \mathbb{R}$. This allows us to represent our virtual constraints as:

$$y(x) = y_a(x) - y_{\text{des}}(\tau(x), \alpha)$$

Therefore, achieving the objective $y \rightarrow 0$ as $t \rightarrow \infty$ implies that $y_a \rightarrow y_{\text{des}}$ as $t \rightarrow \infty$.

Bezier Polynomials: In the context of robotic systems, it is often useful to parameterize desired motions using a polynomial parameterization. One of the most popular choices is Bezier polynomials¹. A Bezier polynomial of degree M is defined as:

$$\begin{aligned} y_d(t, \alpha)_i &= \sum_{k=0}^M \frac{M!}{k!(M-k)!} \alpha_{k,i} t^k (1-t)^{M-k} \\ &= \sum_{k=0}^M \underbrace{\binom{M}{k}}_{\text{binom.}} \underbrace{\alpha_{k,i}}_{\text{coeff.}} \underbrace{t^k (1-t)^{M-k}}_{\text{polynom. term}} \end{aligned}$$

¹ For a great interactive tutorial on Bezier polynomials see <https://pomax.github.io/bezierinfo/>

where $\alpha_{k,i}$ are called the control points of the Beziér curve.

Parameterization of Time: In the case of robotic walking, we can parameterize time as the forward evolution of a walking robot through a step. Explicitly, this is done by defining a function $\tau : D \rightarrow \mathbb{R}$:

$$\tau(x) = \frac{\theta(q) - \theta^+}{\theta^- - \theta^+}$$

where $\theta : D \rightarrow \mathbb{R}$ is a phase variable quantifying the forward progression of the robot (it must be monotonic), $\theta^+ = \theta(x^+)$ is its value at the “beginning” of the step, and $\theta^- = \theta(x^-)$ is its value at the “end” of the step. One common choice for θ is the angle of the stance leg with respect to the vertical axis.

Figure 1: Figure 6 of [Grizzle et al., 2014]

Feedback Linearization

We will begin by considering SISO (single input single output) systems. These are systems with $k = m = 1$ wherein the system takes the form:

$$\begin{aligned}\dot{x} &= f(x) + g(x)u \\ y &= h(x)\end{aligned}$$

with $x \in D \subseteq \mathbb{R}^n$, $u \in U \subset \mathbb{R}$, and $h : D \rightarrow \mathbb{R}$.

Definition: Feedback Linearizable. A control system is feedback linearizable (or input-state linearizable) if there exists a diffeomorphism $z = T(x)$ and a feedback control law $u : D \times U \rightarrow U$ (i.e., $u(x, v)$) such that the closed loop system:

$$\dot{x} = f(x) + g(x)u(x, v)$$

with $v \in \mathbb{R}$ being a new control input, renders a linear relationship between the input and the state:

$$\dot{z} = Az + Bv$$

Since v is an *auxiliary input*, it can be chosen to stabilize the system dynamics (x) which are now linear.

However, sometimes (such as the case with tracking control) it is more beneficial to linearize the input-output map rather than the input-state map. This is called *input-output linearization*.

Definition: Input-Output Linearizable. A control system is input-output linearizable if there exists a feedback control law $u : D \times U \rightarrow U$ (i.e., $u(x, v)$) such that the closed loop system:

$$\dot{x} = f(x) + g(x)u(x, v)$$

with $v \in \mathbb{R}$ being a new control input, renders a linear relationship between the input and the output:

$$y^{(p)} = v$$

with p denoting the *relative degree* of the system.

In this case, since v is an *auxiliary input*, it can be chosen to stabilize the output dynamics (y) which are now linear.

Feedback Linearization Example ²: Let's consider an inverted pendulum with torque actuation at the pivot point:

² Example code can be found [online](#)

$$\dot{x} = \begin{bmatrix} x_2 \\ -\frac{g}{l} \sin(x_1) \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} u$$

with $x_1 = \theta$ being the angle (measured from the downward vertical) and $x_2 = \dot{\theta}$ being the angular velocity.

Our control objective is to drive the pendulum to the upright position $\theta = \pi$, encoded by:

$$y = h(x) = x_1 - \pi$$

This system can be feedback linearized by choosing the control law $u = \frac{g}{l} \sin(x_1) + v$. Plugging this into the system dynamics yields the

closed-loop system:

$$\dot{x} = \begin{bmatrix} \dot{x}_2 \\ v \end{bmatrix} = \underbrace{\begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}}_A x + \underbrace{\begin{bmatrix} 0 \\ 1 \end{bmatrix}}_B v$$

To go further, we can select $v = -k_p y - k_d \dot{y}$ to both stabilize the closed-loop system (for the shifted system $\tilde{x} = x - (\pi, 0)$ such that the equilibrium point is at the origin) and to drive the output to zero. This results in the closed-loop system:

$$\dot{\tilde{x}} = \underbrace{\begin{bmatrix} 0 & 1 \\ -k_p & -k_d \end{bmatrix}}_{A_{cl}} \tilde{x}$$

Thus, we can stabilize our system by choosing k_p and k_d such that the eigenvalues of A_{cl} have negative real parts.

We can also analyze the behavior of the output dynamics:

$$y = x_1 - \pi$$

$$\dot{y} = \dot{x}_1 = x_2$$

$$\ddot{y} = \dot{x}_2 = v$$

Thus, the same conditions can be enforced on k_p and k_d to stabilize the second-order output dynamics:

$$\ddot{y} - k_d \dot{y} - k_p y = 0$$
